Contrasts

December 30, 2017

Contrasts are the way that R (and other statistical software) sets up tests of differences between different groups in an experimental or observational study. Equivalently, they are the way to define the parameters of a linear model that involves categorical predictors.

There are lots of ways to use built-in R functions to define different contrasts, but sometimes we want to define our own custom contrasts. In any case, understanding how to set up your own contrast matrix helps you understand how the built-in functions work.

R's default set of definitions is called *treatment contrasts*. For example, in a linear model with a single categorical predictor (equivalent to a one-way ANOVA), the parameters β_i would be defined as:

```
\beta_0 = \mu_1 = \text{intercept} = \text{predicted value of group 1}
\beta_1 = \mu_2 - \mu_1 = \text{pred. value of group 2} - \text{pred. value of group 1}
\beta_2 = \mu_3 - \mu_1 = \text{pred. value of group 3} - \text{pred. value of group 1}
(1)
```

and so on.

This is equivalent to

```
predicted value of group 1 = \mu_1 = \beta_0

predicted value of group 2 = \mu_2 = \beta_0 + \beta_1

predicted value of group 3 = \mu_3 = \beta_0 + \beta_2 (2)
```

. .

In the treatment contrast case it's reasonably straightforward to see how to get from the first set of equations (defining the parameters, or β values, in terms of differences between predicted values (μ), or group means) to the second set (defining the predicted values in terms of the parameters), but it's not always so straightforward. (If you don't see it immediately, try adding the first two equations in eq. 1 to get the second equation in eq. 2.)

The first set (parameters in terms of group differences) is the more natural way to think about which comparisons we want to test statistically; unfortunately, the second set (group differences in terms of parameters) is the way that R wants us to tell it which comparisons to make.

However, we can write down the second set of equations as the product of a *contrast matrix C* and the parameter vector $\vec{\beta}$ =

 $(\beta_0, \beta_1, \beta_2, \ldots)$:

$$C\vec{\beta} = \begin{pmatrix} 1 & 0 & 0 & \dots \\ 1 & 1 & 0 & \dots \\ 1 & 0 & 1 & \dots \\ \vdots & \vdots & \vdots & \ddots \end{pmatrix} \begin{pmatrix} \beta_0 \\ \beta_1 \\ \beta_2 \\ \dots \end{pmatrix} = \begin{pmatrix} \mu_1 \\ \mu_2 \\ \mu_3 \\ \dots \end{pmatrix}$$
(3)

Now we can do some linear algebra (or ask R to do it) in order to go from the human-friendly to the R-friendly specification of contrasts. Specifically, if we denote the vector of predicted values as $\vec{\mu}$, then R wants us to specify the contrast matrix C such that

$$\vec{\mu} = C\vec{\beta}.\tag{4}$$

We need to solve this equation for $\vec{\beta}$, so that we can specify $\vec{\beta}$ in terms of linear relationships among the $\vec{\mu}$ values. Mathematically, we solve equation 4 by multiplying both sides by the inverse of C:

$$C^{-1}\vec{\mu} = C^{-1}C\vec{\beta}$$

$$= \vec{\beta}.$$
(5)

If we take the matrix C from eq. 3 above and invert it (solve() does matrix inversion in R):

Comparing these values to the relations in eq. 1, we can see that we have successfully recovered C^{-1} such that

$$C^{-1}\vec{\mu} = \begin{pmatrix} 1 & 0 & 0 & \dots \\ -1 & 1 & 0 & \dots \\ -1 & 0 & 1 & \dots \\ \vdots & \vdots & \vdots & \ddots \end{pmatrix} \begin{pmatrix} \mu_1 \\ \mu_2 \\ \mu_3 \\ \dots \end{pmatrix} = \begin{pmatrix} \beta_0 \\ \beta_1 \\ \beta_2 \\ \dots \end{pmatrix}$$
(6)

A more complex example

A common situation is that we want to test whether the combination of two treatments has more or less effect than either treatment alone. This is different from the typical setup for a two-way interaction, discussed below, where the null hypothesis is that the combination of the two treatments has an additive effect. This occurred in There are four treatments: we know the amount of predation in the control treatment (μ_1), crabs-only treatment (μ_2), shrimp-only treatment (μ_3), and crabs-plus-shrimp treatment (μ_4). Suppose we want to parameterize this model in terms of

- the overall mean predation level: $(\mu_1 + \mu_2 + \mu_3 + \mu_4)/4$
- the average effect of symbionts, i.e. the difference between the control (μ_1) and the average of the symbiont treatments ($\mu_2 + \mu_3 + \mu_4$)/3
- the difference between crabs and shrimp, $\mu_2 \mu_3$
- the difference between the combined-symbiont treatment, μ_4 , and the average of the single-symbiont treatments, $(\mu_2 + \mu_3)/2$

The signs are set up to allow for the fact that we want to quantify the *decrease* in predation under symbiont prediction.

Define cc_inv as follows:

##		intercept	avg_symb	C.vs.S	twosymb	
##	none	1/4	1/4	1/4	1/4	
##	C	1	-1/3	-1/3	-1/3	
##	S	0	1	-1	Θ	
##	CS	0	1/2	1/2	-1	

This is what we get for C by inverting C^{-1} (solve(cc_inv)) (with a little bit of cosmetic stuff): *Not sure why I have to transpose the result here?*?

##		intercept	${\rm avg_symb}$	C.vs.S	twosymb	
##	none	1	1	1	1	
##	С	3/4	-1/4	-1/4	-1/4	
##	S	0	1/2	-1/2	0	
##	CS	0	1/3	1/3	-2/3	

Crawley (2002) gives another custom-contrast example, but he pretty much just shows *C* without much discussion of how one would derive it.

Categorical predictors: contrasts

Independent contrasts.

The *contrast matrix* determines what a given row of the design matrix (for level *i* of a categorical variable) looks like.

$$\bar{y} = C\beta$$

Set contrasts in general via options() or per-factor via contrasts(), or within the model statement, e.g.

```
d <- data.frame(f=c("a","a","a","b","b","b"),y=c(1,1,1,3,3,3))</pre>
coef(lm(y~f,data=d))
## (Intercept)
                         fb
                          2
##
             1
coef(lm(y~f,data=d,contrasts=list(f="contr.sum")))
## (Intercept)
                         f1
##
                         - 1
  Or:
contrasts(d$f) <- "contr.sum"</pre>
## or (slightly dangerous because it sets the options
## *globally*, sometimes leading to confusion)
options(contrasts=c("contr.sum", "contr.poly"))
  Reordering factors: levels, reorder, relevel
levels(relevel(d$f, "b"))
## [1] "b" "a"
levels(with(d,reorder(f,y,mean)))
## [1] "a" "b"
```

In general requesting a contrast for an n-level factor gets us only an $n \times (n-1)$ matrix: the first column is an implicit intercept (all-1) column.

Treatment contrasts (default: "dummy", "corner-point")

First level of factor (often alphabetical!) is the default intercept/baseline for contr.treatment (default): contr.SAS uses the *last* level of the factor (which is SAS's default). You can specify a baseline via contr.treatment(n,base=b), but it may make more sense to relevel the factor to put the baseline (typically control) treatment first. The full contrast matrix is not orthogonal (i.e. C^TC is not diagonal: we want $C_i^TC_j = 0$ whenever $i \neq i$).

TODO explain more about what orthogonality means and why we would care

```
(cc <- contr.treatment(4))</pre>
     2 3 4
##
## 1 0 0 0
## 2 1 0 0
## 3 0 1 0
## 4 0 0 1
  The comparisons between treatments and the baseline are all or-
thogonal to each other,
is_orthog <- function(x) {</pre>
    xsq <- t(x) %*% x
    return(all(xsq-diag(diag(xsq))==0) && ## off-diagonals are zero
         all(diag(xsq)!=0))
}
is_orthog(cc)
## [1] TRUE
cc <- cbind(1,cc) ## add intercept column</pre>
is_orthog(cc)
## [1] FALSE
  If we want to know the meaning of \beta, it's easiest to invert:
                              \boldsymbol{\beta} = \boldsymbol{C}^{-1} \bar{\boldsymbol{y}}
solve(cc)
##
       1 2 3 4
##
      1 0 0 0
## 2 -1 1 0 0
## 3 -1 0 1 0
## 4 -1 0 0 1
  Example (from Gotelli and Ellison (2004)):
ants <- data.frame(</pre>
    place=rep(c("field", "forest"), c(6,4)),
    colonies=c(12, 9, 12, 10,
                 9, 6, 4, 6, 7, 10))
mean(ants$colonies[ants$place=="field"])
## [1] 9.666667
mean(ants$colonies[ants$place=="forest"])
```

```
## [1] 6.75
pr <- function(m) printCoefmat(coef(summary(m)),digits=3,signif.stars=FALSE)</pre>
pr(lm1 <- lm(colonies~place,data=ants))</pre>
##
                Estimate Std. Error t value
## (Intercept)
                   9.667
                               0.958
                                        10.09
## placeforest
                  -2.917
                               1.515
                                        -1.92
##
                Pr(>|t|)
## (Intercept)
                   8e-06
                    0.09
## placeforest
```

The (Intercept) row refers to β_1 , which is the mean density in the "field" sites ("field" comes before "forest"). The placeforest row tells us we are looking at the effect of the place variable on the forest level, i.e. the difference between the "forest" and "field" sites. (The only ways we could know that "field" is the baseline site are (1) to remember, or look at levels (ants\$place) or (2) to notice which level is *missing* from the list of parameter estimates.)

Helmert

In this case the full matrix (intercept and all comparisons) is orthogonal (which is why Helmert were the default contrasts in R's ancestor, S-PLUS), but the comparisons are less intuitive.

```
(cc <- cbind(1,contr.helmert(4)))</pre>

## placeforest 0.00043
```

Sometimes clearer (and we get confidence intervals etc. on the predictions for each level), but the hypotheses tested are rarely interesting (is the mean of each level equal to zero?)

More generally, if you want to compute the group means, you can

```
• Use the predict function:
predict(lm1,newdata=data.frame(place=c("field","forest")),interval="confidence")
• Use effects::allEffects:
summary(allEffects(lm1))
Use emmeans::emmeans:
emmeans(lm1,spec=~place)
  Forward difference contrasts:
(cc <- cbind(mean=1,MASS::contr.sdif(4)))</pre>

```

Exercise: How would you construct a version of 'contr.sum' where the first, not the last, level is aliased/dropped?

Things get slightly more interesting/complicated when we have more than two levels of a categorical variable. I'll look at some data on lizard perching behaviour, from the 'brglm' package (and before that from McCullagh and Nelder (1989), ultimately from Schoener (1970). I'm going to ignore the fact that these data might best be fitted with generalized linear models.

A quick look at the data: response is number of Anolis grahami lizards found on perches in particular conditions.

For a moment we're going to just look at the time variable. If we leave the factors as is (alphabetical) then β_1 ="early", β_2 ="late"-"early", β_3 ="midday"-"early". At the very least, it probably makes sense to change the order of the levels:

```
lizards$time <- factor(lizards$time,levels=c("early","midday","late"))</pre>
```

All this does (since we haven't changed the baseline factor) is swap the definitions of β_2 and β_3 .

In a linear model, we could also use sum-to-zero contrasts:

pr(lm(grahami~time, data=lizards, contrasts=list(time=contr.sum)))

```
Estimate Std. Error t value
##
## (Intercept)
                               3.53
                                        5.47
                   19.30
## time1
                   -1.67
                                4.93
                                       -0.34
## time2
                   12.85
                               5.10
                                        2.52
##
                Pr(>|t|)
## (Intercept) 2.4e-05
## time1
                    0.74
## time2
                    0.02
```

Now the (Intercept) parameter is the overall mean: time1 and time2 are the deviations of the first ("early") and second ("midday") transparent.

There are other options for contrasts such as MASS::contr.sdif(), which gives the successive differences between levels.

contrasts for all variables), but the way shown above may be the most

```
pr(lm(grahami~time,data=lizards,contrasts=list(time=contr.sdif)))
```

```
##
               Estimate Std. Error t value
                               3.53
                                       5.47
## (Intercept)
                  19.30
## time2-1
                  14.52
                               8.74

## time3-2
                 -24.02
                               8.74
                                      -2.75
##
               Pr(>|t|)
## (Intercept) 2.4e-05
## time2-1
                  0.112
## time3-2
                  0.012
```

You might have particular contrasts in mind (e.g. "control" vs. all other treatments, then "low" vs "high" within treatments), in which case it is probably worth learning how to set contrasts. (We will talk about testing *all pairwise differences later*, when we discuss multiple comparisons. This approach is probably not as useful as it is common.)

Multiple treatments and interactions

Additive model

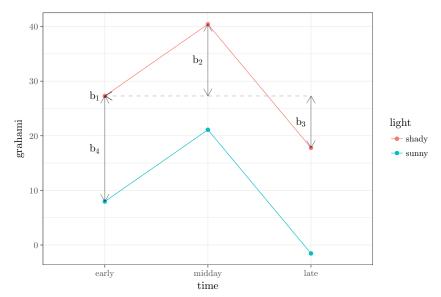

Let's consider the light variable in addition to time.

pr(lmTL1 <- lm(grahami~time+light,data=lizards))</pre>

```
Estimate Std. Error t value
##
## (Intercept)
                  27.29
                               5.63
                                       4.85
## timemidday
                  13.14
                               7.11
                                       1.85
## timelate
                  -9.50
                               6.85
                                      -1.39
## lightsunny
                 -19.32
                               5.73
                                      -3.37
##
               Pr(>|t|)
## (Intercept) 0.00011
## timemidday
                0.08010
## timelate
                0.18174
## lightsunny
                0.00321
```

Here's a graphical interpretation of the parameters:

Loading required package: grid

 β_1 is the intercept ("early", "sunny"); β_2 and β_3 are the differences from the baseline level ("early") of the *first* variable (time) in the *baseline* level of the other parameter(s) (light="shady"); β_4 is the difference from the baseline level ("sunny") of the *second* variable (light) in the *baseline* level of time ("early").

Now let's look at an interaction model:

pr(lmTL2 <- lm(grahami~time*light,data=lizards))</pre>

##		Estimate	Std. Error
##	(Intercept)	23.50	5.38
##	timemidday	27.75	7.60
##	timelate	-12.75	7.60
##	lightsunny	-11.75	7.60
##	$\verb timemidday:lightsunny \\$	-32.83	11.19
##	timelate:lightsunny	6.50	10.75
##		t value I	Pr(> t)
	(Intercept)	t value 4.37	Pr(> t) 0.00042
##	(Intercept) timemidday		
## ##		4.37	0.00042
## ## ##	timemidday	4.37 3.65	0.00042 0.00198
## ## ## ##	timemidday timelate	4.37 3.65 -1.68	0.00042 0.00198 0.11180

Parameters β_1 to β_4 have the same meanings as before. Now we also have β_5 and β_6 , labelled "timemidday:lightsunny" and "timelate:lightsunny", which describe the difference between the expected mean value of these treatment combinations based on the additive model (which are $\beta_1 + \beta_2 + \beta_4$ and $\beta_1 + \beta_3 + \beta_4$ respectively) and their actual values.

Now re-do this for sum-to-zero contrasts ... the fits are easy:

time2:light1

12.028

```
pr(lmTL1S <- update(lmTL1,contrasts=list(time=contr.sum,light=contr.sum)))</pre>
```

```
##
                Estimate Std. Error t value
## (Intercept)
                   18.84
                                2.87
                                        6.57
## time1
                   -1.21
                                4.01
                                       -0.30
                   11.92
## time2
                                4.15
                                        2.87
## light1
                    9.66
                                2.87
                                        3.37
##
                Pr(>|t|)
## (Intercept) 2.7e-06
## time1
                  0.7654
## time2
                  0.0097
## light1
                  0.0032
pr(lmTL2S <- update(lmTL2,contrasts=list(time=contr.sum,light=contr.sum)))</pre>
##
                 Estimate Std. Error t value
## (Intercept)
                   18.236
                                2.255
                                         8.09
## time1
                   -0.611
                                3.146
                                        -0.19
## time2
                   10.722
                               3.271
                                         3.28
## light1
                                         4.55
                   10.264
                                2.255
## time1:light1
                   -4.389
                                3.146
                                        -1.39
```

3.271

3.68

```
## Pr(>|t|)
## (Intercept) 3.1e-07
## time1 0.84830
## time2 0.00444
## light1 0.00028
## time1:light1 0.18100
## time2:light1 0.00187
```

(The intercept doesn't stay exactly the same when we add the interaction because the data are unbalanced: try with(lizards,table(light,time)))
